During this period, the current through thyristor is also zero. Therefore, circuit turn off time is $t_c = [(2\pi - \alpha) / \omega]$ second. This time must be greater than the thyristor turn-off time otherwise thyristor may turn on at undesired instant and will lead to commutation failure. Calculation of Steady Load Current:

Influence of source inductor L_s and load voltage V_{load} . As with the single-phase diode rectifier, a source inductance L_s larger than zero leads to a current commutation interval between the thyristor pairs T_1/T_2 and T_3/T_4 . This interval adds to the thyristor firing angle α and leads to a further reduction of the average load voltage.

The maximum output voltage across the load is obtained when firing angle $\alpha = 0$. Single-phase Half Wave Controlled Rectifier with RL Load : When the load is complex i.e., when the load contains any energy storage elements like inductor (RL load), the situation becomes different from that of pure resistive load.

The isolation transformer and the load and batteries are completely isolated from the grid system. Thyristor control ensures fast regulation and voltage distortions in the mains do not affect the batteries and loads.

For Resistive Load In the case of a three-phase half wave controlled rectifier with resistive load, the thyristor T_1 is triggered at $\omega t = (30^\circ + \alpha)$ and T_1 conducts up to $\omega t = 180^\circ$. When the phase supply voltage decreases to zero, the load current falls to zero and the thyristor T_1 turns off. Thus T_1 conducts from $\omega t = (30^\circ + \alpha)$ to $(180 \dots$
